Anti-inflammatory peptides

## ABSTRACT

Peripheral artery disease is an atherosclerotic stenosis in the peripheral vasculature that is typically treated via percutaneous transluminal angioplasty. Deployment of the angioplasty balloon damages the endothelial layer, exposing the underlying collagen and allowing for the binding and activation of circulating platelets which initiate an inflammatory cascade leading to eventual restenosis. Here, we report on collagen-binding sulfated poly(N-isopropylacrylamide) nanoparticles that are able to target to the denuded endothelium. Once bound, these nanoparticles present a barrier that reduces cellular and platelet adhesion to the collagenous surface by 67% in whole blood and 59% in platelet-rich plasma under biologically relevant shear rates. *In vitro* studies indicate that the collagen-binding nanoparticles are able to load and release therapeutic quantities of anti-inflammatory peptides, with the particles reducing inflammation in endothelial and smooth muscle cells by 30% and 40% respectively. Once bound to collagen, the nanoparticles increased endothelial migration while avoiding uptake by smooth muscle cells, indicating that they may promote regeneration of the damaged endothelium while remaining anchored to the collagenous matrix and locally releasing anti-inflammatory peptides into the injured area. Combined, these collagen-binding nanoparticles have the potential to reduce inflammation, and the subsequent restenosis, while simultaneously promoting endothelial regeneration following balloon angioplasty.

## Statement of Significance

In this manuscript, we present our work on the development and characterization of a novel temperature sensitive collagen-binding nanoparticle system. We demonstrate that when bound to a collagenous matrix, the nanoparticles are able to promote endothelial migration while avoiding cellular uptake. We also show that the nanoparticles are able to reduce inflammation via the release of anti-inflammatory peptides which, when combined with its ability to inhibit platelet binding, could lead to reduced intimal hyperplasia following balloon angioplasty. The drug delivery platform presented represents a unique dual therapy biomaterial wherein the nanoparticle itself plays a crucial role in the system's overall therapeutic potential while simultaneously releasing anti-inflammatory peptides.

## 1. Introduction

Peripheral artery disease (PAD) is characterized by an atherosclerotic stenosis within the peripheral vasculature. Despite improved screening effectiveness, PAD still affects over 25% of adults over 55, and is even more prevalent in patients with

cardiovascular risk factors such as smoking and hypertension [1–6]. Additionally, PAD is associated with increased risk of other cardiovascular diseases, making the development of an effective long-term treatment of paramount importance to the large population that lives with this disease [7,8].

The current standard of treatment for severe PAD is percutaneous transluminal angioplasty, sometimes coupled with stent deployment to hold open the widened vessel. A major drawback of angioplasty is that balloon deployment damages the vessel wall, thus exposing the underlying collagenous matrix [9]. Circulating platelets can then bind to the sub-endothelial collagen and become

activated, releasing a host of pro-inflammatory factors including epidermal growth factor (EGF), IL-1 $\beta$ , and platelet derived growth factor (PDGF) [10–12]. Smooth muscle cells (SMC) exposed to these factors then become activated and proliferative, resulting in intimal hyperplasia and eventual restenosis, or narrowing of the vessel wall [13–17]. This process is further accelerated by pro-inflammatory cytokines released by the activated SMC, including tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 $\beta$  (IL-1 $\beta$ ), interleukin-8 (IL-8) and interleukin-6 (IL-6) [18–20]. The development of restenosis can lead to peripheral limb ischemia, with treatment often necessitating a second angioplasty procedure to open the re-occluded vessel.

Rather than treating restenosis by attenuating the inflammatory cascade, current surgical methods utilize drug-loaded stents that release cytostatic compounds such as paclitaxel and sirolimus to combat the inflammation-induced cellular proliferation. While they are effective at inhibiting intimal hyperplasia [21–24], these compounds are untargeted and thus inhibit the proliferation of local endothelial cells along with the SMC [22,23]. This results in incomplete healing of the treated area, leaving the stent and collagenous tissue chronically exposed and leading to long-term complications such as late stent thrombosis [25,26]. Additionally, stents deployed in the peripheral vasculature have a high fracture rate due to the higher crushing and torsional forces they experience [27–29]. These issues make drug-eluting stents a sub-optimal method to prevent restenosis following angioplasty. Thus there exists a need for an improved treatment system that can be deployed during angioplasty to attenuate the subsequent inflammation and promote healing of the damaged vessel.

We have previously reported on a cell penetrating anti-inflammatory peptide (KAFAKLAARLYRKALARQLGVAA abbreviated KAFAK) that can reduce the expression of pro-inflammatory cytokines, by inhibiting mitogen-activated protein kinase activated protein kinase 2 (MK2) [30]. MK2 increases the production of pro-inflammatory cytokines, such as TNF- $\alpha$  and IL-6, regulating inflammation in several diseases, including atherosclerosis [31–35]. While KAFAK has been effective at reducing pro-inflammatory cytokine levels, poor bioavailability in the presence of serum proteases limits its efficacy [36–38]. Therefore it is desirable to use a delivery system that can protect the peptide from proteolytic degradation while providing a sustained release profile *in vivo*, thereby increasing KAFAK's therapeutic efficacy while providing local delivery to the injured area [38–40].

Poly(N-isopropylacrylamide) (pNIPAM) is a thermosensitive polymer that has been extensively studied in biological applications as it exhibits a physiologically relevant lower critical solution temperature (LCST) around 33 °C [41–47]. At temperatures below the LCST, crosslinked pNIPAM microgels are in a swollen hydrophilic state, allowing for the loading of water-soluble therapeutics via passive diffusion. Above the LCST, the particle then undergoes hydrophobic collapse, entrapping the loaded drug and allowing for a controlled diffusion out of the particle [38,40,47]. In addition, pNIPAM is readily copolymerized with other monomers such as acrylic acid (AAC) to provide easily modified functional groups. Bartlett et al. reported that the addition of the sulfated monomer 2-acrylamido-2-methyl-1-propanesulfonic acid (AMPS) to the NIPAM backbone results in a charged nanoparticle that offers increased loading of cationic therapeutics via electrostatic attraction [38,40]. Additionally, loading the peptide into the nanoparticle provided protection from proteolytic degradation while reducing osteoarthritic inflammation [48]. However these particles were untargeted, allowing them to diffuse away from the site of injury, thus limiting their potential for targeted release. This limitation can be overcome by modifying the delivery system with a targeting ligand that is specific to the damaged area. A particle successfully targeted to the balloon-injured vessel would be able to bind to

the damaged area, and remain bound in the presence of blood flow, while locally releasing anti-inflammatory peptides to attenuate the inflammatory cascade.

We have reported on a collagen I binding peptide (RRANAALK-AGELYKSILYGC abbreviated SILY) that has been shown to bind to type 1 collagen and prevent platelet adhesion and activation when attached to a dermatan sulfate backbone, while reducing intimal hyperplasia and platelet adhesion *in vivo* [49,50]. Additionally, pNIPAM nanoparticles modified with SILY have been shown to bind to collagen and prevent platelet activation while still providing a sustained release of their loaded peptide [51]. However, these studies were conducted in a static environment and did not investigate their efficacy *in vitro*. Here, we show that SILY-modified pNIPAM nanoparticles are effective at inhibiting platelet binding under biologically relevant flow conditions, and are capable of binding to SMC-elaborated collagen *in vitro*. Additionally, KAFAK-loaded nanoparticles effectively inhibit inflammation in endothelial cells (EC) and SMC while inhibiting platelet adhesion and demonstrating minimal cytotoxicity.

## 2. Materials and methods

### 2.1. Nanoparticle synthesis

pNIPAM containing 5 mol% 2-acrylamido-2-methyl-1-propane sulfonic acid (AMPS) and 1 mol% Acrylic Acid (AAc) were synthesized in a precipitation polymerization reaction as described previously [44,51]. Briefly, 794.1 mg of NIPAM (Thermo Fisher Scientific), 28.5 mg of N,N'-methylenebisacrylamide (MBA, Sigma-Aldrich), and 76.5 mg of AMPS (Sigma-Aldrich) were added to 70 °C MilliQ water (18.2 M $\Omega$ -cm resistivity, Millipore) that had been refluxed under nitrogen for 30 min. 5  $\mu$ L of AAc (99.5%, Thermo Fisher Scientific) and 164  $\mu$ L of sodium dodecyl sulfate (SDS, 10% w/v, Sigma-Aldrich) were added to the solution, and polymerization was initiated by the addition of 33.7 mg of potassium persulfate (Sigma-Aldrich). For fluorescent nanoparticle synthesis, 1 mol% fluorescein o-acrylate was pre-dissolved in 3% DMSO and then added to the shell polymer mixture and allowed to equilibrate for 30 min before the initiation of polymerization. After 5 h, the reaction was cooled to room temperature and then dialyzed against MilliQ water for 7 days using a 15,000 MWCO dialysis membrane (Spectra-Por). Following dialysis, the purified poly(NIPAM-MBA-AMPS-AAc) nanoparticles were lyophilized and stored at room temperature.

### 2.2. Fabrication of peptide-modified nanoparticles

Collagen binding nanoparticles were fabricated by using 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) and the heterobifunctional cross linker N- $\beta$ -Maleimidopropionic acid hydrazide (BMPH) to crosslink SILY to the carboxylic acid groups of present in the nanoparticle, as described previously with slight modification [51]. First, lyophilized poly(NIPAM-MBA-AMPS-AAc) nanoparticles were activated by dissolving them in a coupling buffer consisting of 0.1 M MES (Sigma-Aldrich), 0.5 M NaCl (Sigma-Aldrich) and 0.4 mg/mL EDC (Thermo Fisher Scientific) at pH 6.0. After 15 min, a 1:1 M equivalent of BMPH (BMPH:AAc) was then added to the solution and allowed to shake at room temperature for 30 min. The BMPH conjugated nanoparticles (NP-BMPH) were purified by centrifugation at 18,000g and 25 °C for 60 min. The pelleted particles were rinsed with MilliQ water and then lyophilized.

For SILY attachment, lyophilized NP-BMPH were then dissolved at 1 mg/mL in 1X PBS, and 1% of the total concentration of the collagen binding peptide RRANAALKAGELYKSILYGC (SILY, 80% purity,

Genscript) was added as Sily<sub>biotin</sub> and allowed to shake at room temperature for 45 min. The remaining peptide was then added and allowed to react for an additional 120 min, to create the Sily-modified nanoparticles (NP-Sily). For particles without Sily<sub>biotin</sub>, the entire amount of Sily was added and allowed to react for 3 h. The modified particles were purified by centrifugation and resuspension, as described above, and then lyophilized. Non-collagen-binding particles were made using the peptide GVDVDQDGETGC (LFA, 78% purity, Genscript) and following the same protocol.

### 2.3. Cell culture

Human aortic endothelial cells were grown continually as a monolayer in medium 200 (ThermoFisher Scientific) supplemented with low serum growth supplement (ThermoFisher Scientific) consisting of 1 µg/mL hydrocortisone, 10 ng/mL epidermal growth factor, 3 ng/mL basic fibroblast growth factor, and 10 µg/mL heparin and 2% fetal bovine serum (FBS). Human coronary artery smooth muscle cells (SMC) were grown continually as a monolayer in medium 231 (ThermoFisher Scientific) supplemented with smooth muscle growth supplement (ThermoFisher Scientific) consisting of 2 ng/mL basic fibroblast growth factor, 0.5 ng/mL epidermal growth factor, 5 ng/mL heparin, 2 µg/mL recombinant human insulin-like growth factor, 0.2 µg/mL bovine serum albumin (BSA) and 4.9% FBS. All cells were maintained at 37 °C and 5% CO<sub>2</sub> and used between passages 3 and 8.

### 2.4. Endothelial cell migration

In order to ensure that NP-Sily does not adversely impact endothelial migration, we used Oris migration kits (Platypus technologies) to measure cellular proliferation after treatment with varying concentrations of modified nanoparticles. For migration on a collagen coated surface, human type I collagen (chronolog) was diluted in isotonic glucose and added to an Oris 96-well plate at a concentration of 10 µg/cm<sup>2</sup> and incubated overnight at 4 °C. The collagen solution was removed from the wells and the plate was air dried under UV for 24 h. The supplied stoppers were inserted into the wells to prevent cellular adhesion to the center of the wells. Endothelial cells were then seeded at 8000 cells/well and allowed to grow to confluence for 36 h. The stoppers were then removed, the wells were washed to remove unbound cells, and 100 µL of complete media containing 0, 1, 2, or 4 mg/mL NP-Sily was added to each well. For collagen coated plates, wells were rinsed with media after 30 min to remove unbound particles. Cells were then allowed to migrate for 24 h before being stained with 10 µM CellTracker green (ThermoFisher Scientific) in media for 30 min at 37 °C. Stained cells were rinsed with PBS and the Oris plate mask was added to isolate the previously blocked area of the plate. Fluorescence was then read on Spectramax M5 plate reader at 492 nm excitation and 517 nm emission. Visualization of endothelial migration was performed with a Zeiss Observer Z1 fluorescent microscope.

### 2.5. NP-Sily binding to collagen *in vitro*

In order to verify NP-Sily's ability to bind to naturally elaborated collagen, we treated proliferative smooth muscle cells with modified nanoparticles. First, SMC were seeded at 50,000 cells/cm<sup>2</sup> on an 8 chambered glass slide (Lab-Tek) and allowed to bind for 24 h. 200 µL of complete media containing 2, 1, or 0 mg/mL of fluorescent NP-Sily or NP-Sily<sub>biotin</sub> was then added to the chambers and allowed to incubate for 30 min or 24 h before being rinsed 3X with media to remove unbound particles. Fluorescent NP-Sily

was used for qualitative images of binding to collagen, while biotinylated NP-Sily provided parallel quantitative assessments of binding.

For studies using biotinylated particles, media was removed and 100 µL of a diluted streptavidin solution (R & D Systems) was added to each well and incubated on a plate shaker at 200 RPM and room temperature for 20 min. The plate was rinsed with PBS and 100 µL of a reagent color solution (R & D Systems) was added to each well and incubated at 200 RPM and room temperature for 20 min. Finally, 50 µL of 2 N H<sub>2</sub>SO<sub>4</sub> was added to stop the reaction, and absorbance was read at 450 nm and 540 nm on a SpectraMax M5 plate reader. For visualization of fluorescent collagen-bound NP-Sily, cells were imaged on a Zeiss Observer Z1 fluorescent microscope. Semi-quantitative measurements of amount of bound nanoparticles were determined by using ImageJ to measure the fluorescent area of 3 images of each treatment.

### 2.6. NP-Sily cytotoxicity

The biocompatibility of Sily-modified nanoparticles was examined with a Vybrant MTT cell proliferation assay (Molecular Probes) according to manufacturer instructions. First, endothelial and smooth muscle cells were seeded in a 96-well tissue culture plate at 30,000 cells/well and 50,000 cells/well respectively and allowed to adhere for 24 h. The media was removed and fresh media containing varying concentrations of NP-Sily was added to each well and incubated for 24 h. The media was removed and 100 µL of fresh media was added to each well. The MTT reagent was prepared by dissolving in sterile PBS at a concentration of 5 mg/mL, and 10 µL was added to each well and incubated for 4 h at 37 °C. SDS was then dissolved in 0.01 M HCl at a concentration of 100 mg/mL, and 100 µL was added to each well and incubated for 4 h at 37 °C. The absorbance was then read at 570 nm on a Spectramax M5 plate reader.

### 2.7. Peptide loading of NP-Sily

In order to demonstrate the modified nanoparticles ability to deliver therapeutics in an *in vitro* inflammatory culture system, we loaded the nanoparticles with the anti-inflammatory cell penetrating peptide (American Peptide). To load the nanoparticles Sily-modified nanoparticles and KAFK were co-incubated in MilliQ water at final concentrations of 1 mg/mL and 2 mg/mL respectively and stored at 4 °C for 24 h. Loaded nanoparticles were pelleted via centrifugation, and the supernatant was collected for analysis. A fluoroldehyde o-phthalaldehyde (OPA) assay was performed to determine the amount of KAFK loaded into the nanoparticles. Briefly, 1:10 mixtures of sample and fluoroldehyde OPA were created in opaque 96-well plates (VWR), and the fluorescence was measured at an excitation of 360 nm and emission of 455 nm on a SpectraMax M5 plate reader. Values were compared against a standard to determine the amount of KAFK present in the pre and post-load solution.

### 2.8. Prevention of *in vitro* inflammation

Given that platelet activation is an underlying cause of SMC inflammation and proliferation and that mechanical damage from balloon deployment can damage EC and SMC, we investigated the ability of KAFK-loaded NP-Sily to inhibit inflammation in SMC and EC treated with platelet-derived growth factor (PDGF, Peprotech) an inflammatory factor released by activated platelets. SMC were seeded in a 96-well tissue culture plate at a density of 50,000 cells/cm<sup>2</sup> and allowed to adhere for 12 h before being serum starved by incubation in unsupplemented medium 231 for

24 h. Cells were then treated with 10 ng/mL PDGF and either KAFK or KAFK-loaded NP-SILY for 24 h. The media was removed, and the concentration of IL-6 and TNF- $\alpha$  were then measured using an MSD multi-array human cytokine assay kit (MesoScale Discovery) according to manufacturer instructions.

Briefly, 25  $\mu$ L of sample was added to a pre-coated high bind plate, covered, and incubated at on a plate shaker at 700 RPM and room temperature for 2 h. 25  $\mu$ L of detection antibody solution was then added to each well, and the plate was then covered and incubated at 700 RPM for a further 2 h. Finally, the plate was washed 3 times with PBS containing 0.05% tween-20. 150  $\mu$ L of 2X read buffer was added to each well, and the plate was read on a QuickPlex SQ 120 plate reader (MesoScale Discovery).

### 2.9. Prevention of platelet attachment under biologically relevant flow conditions

The ability of NP-SILY to inhibit platelet binding under flow conditions was investigated using collagen-coated IBIDI microchannels to simulate a biological flow environment. First, human monomeric collagen (Chronolog) was diluted in isotonic glucose to a final concentration of 50  $\mu$ g/mL. The collagen solution was then pipetted into the channels of an IBIDI  $\mu$ -slide VI<sup>0.1</sup> slide and incubated overnight at 4 °C. The coated channels were then washed with 100  $\mu$ L of PBS, and then blocked for 30 min at room temperature with 1% BSA in PBS. The channels were again washed with PBS and varying concentrations of NP-SILY were added to the channels and incubated at 37 °C for 30 min before being washed a final time.

15 mL of whole blood was collected into citrated vacutainers from healthy volunteers by venipuncture following an approved Purdue IRB protocol and with informed consent. The blood was centrifuged for 20 min at 200G and 25 °C and the top layer of platelet-rich plasma (PRP) was collected. PRP and whole blood was then loaded into 3 mL syringes and a syringe pump was used to flow the fluid through the channel at a rate of 2.1 mL/hr, yielding a physiologically relevant shear rate of 375 s<sup>-1</sup> [52]. After 30 min, the channels were washed with 100  $\mu$ L of PBS and adherent cells were stained with CellTracker Green using the protocol mentioned previously. Flow channels were imaged on a Zeiss Observer Z1 fluorescent microscope. Three images were taken of each channel, and ImageJ was used to measure total fluorescent area in order to determine the relative binding of cells in each treatment group.

### 2.10. Statistical analysis

Statistical significance was determined using a one-way ANOVA with a Tukey post-hoc test to compare experimental groups. A significance level of  $\alpha = 0.05$  was used for all comparisons and all data is expressed as mean  $\pm$  standard deviations.

## 3. Results

### 3.1. Nanoparticle cytotoxicity

In order to remain viable *in vivo* drug delivery platforms, the modified nanoparticles must remain biocompatible at concentrations necessary to release therapeutic levels of KAFK. The MTT assay indicates that there were no significant differences in cellular viability of endothelial (Fig. 1a) or smooth muscle cells (Fig. 1b) treated with up to 8 mg/mL of NP-SILY. This suggests that the nanoparticles can be used to locally deliver therapeutics without inducing a cytotoxic response in the surrounding cells.

**Fig. 1.** Nanoparticle cytotoxicity. Results of an MTT assay on endothelial cells (1A) and smooth muscle cells (1B) treated with varying concentrations of NP-SILY over 24 h at 37 °C.

### 3.2. Endothelial migration

Due to the importance of endothelial migration on the healing of the damaged vessel, we investigated whether varying concentrations of NP-SILY impacted endothelial migration (Fig. 2). As seen in Fig. 2a, modified nanoparticles have no significant impact on endothelial migration on tissue culture plastic at concentrations below 4 mg/mL; however, higher concentrations of NP-SILY significantly decreased cellular migration. Conversely, an increase in cellular migration on a collagen-coated surface was observed at nanoparticle concentrations above 2 mg/mL (Fig. 2b).

### 3.3. In vitro collagen binding

While the SILY-modified nanoparticles have demonstrated the ability to bind to a collagen-coated surface [51], it is equally important that they have the capability to bind to collagen that is elaborated by the SMC found within the damaged blood vessel. Fig. 3 demonstrates NP-SILY's ability to bind to collagen elaborated by human coronary artery smooth muscle cells 24 h after plating on tissue culture plastic. As seen in the quantitative analysis of NP-SILY<sub>biotin</sub> binding to SMC collagen (Fig. 3a), biotinylated NP-SILY

**Fig. 2.** NP-SILY effect on endothelial migration. Migration of endothelial cells cultured on tissue culture plastic (2A) and a collagen-I coated surface (2B) and treated with varying concentrations of NP-SILY. \*Indicates significance from all other treatments; †indicates significance from untreated control. 2C: Fluorescent images of endothelial cells on a collagen surface after 24 h of migration following treatment with NP-SILY at 0 mg/mL (I), 1 mg/mL (II), 2 mg/mL (III), and 4 mg/mL (IV), scale bar = 250 μm. Red lines indicate edge of cell stopper that was removed prior to migration, while arrows indicate direction of cell migration. binds to the collagen matrix following a short 30-min incubation at the 2 mg/mL concentration, while lower nanoparticle concentrations required a longer incubation to demonstrate the same level of collagen binding. Further, significantly more nanoparticle binding to collagen is seen after 24 h when the SMCs have had time to secrete additional extracellular collagen. Conversely, nanoparticles modified with the non-collagen-binding LFA peptide demonstrated only a small amount of non-specific binding, even after the longer 24-h incubation.

Fig. 3b shows imaging of fluorescently-labeled nanoparticles bound to the SMC matrix. After 30 min of incubation with fluorescent nanoparticles, distinct fiber-like structures are observed on top of the SMC, indicating that NP-SILY successfully binds to the elaborated collagen. After an additional 24 h of culture, fluorescence can be observed farther away from the SMC, indicating that additional particles bound to the collagen as it was newly elaborated. This is further demonstrated in the semi-quantitative analysis of fluorescent images in Fig. 3c, which shows that fluorescence is detectable after an initial 30-min incubation and increases with prolonged incubation, likely due to additional signal from binding to newly elaborated collagen. Finally, after 30 min of NP-SILY exposure, fluorescence at 2 mg/mL is significantly higher than fluorescence at 1 mg/mL, indicating increased nanoparticle binding at higher nanoparticle concentrations, likely attributable to larger concentration gradients driving rapid binding to the collagen.

### 3.4. In vitro inflammatory inhibition

In order to be a viable treatment for post-angioplasty vessel damage, KAFK must be released at therapeutic concentrations at ~30 μM for effective inhibition of inflammation [30]. We investigated KAFK-loaded NP-SILY's ability to inhibit inflammation in endothelial and smooth muscle cells that had been stimulated with PDGF. Fig. 4 shows that the KAFK-loaded nanoparticles were able to reduce inflammation in both cell types, with IL-6 levels decreasing 30% and 40% in endothelial (Fig. 4a) and smooth muscle (Fig. 4b) cells, respectively. The addition of free-KAFK decreased endothelial inflammation by 80% and decreased SMC inflammation by 16%.

### 3.5. Prevention of platelet attachment under biologically relevant flow conditions

Beyond providing a platform for the release of therapeutic peptides, the SILY-modified nanoparticles are designed to have dual-therapy potential by preventing platelet activation by binding to the collagenous matrix exposed by the angioplasty procedure. We tested this ability by flowing whole blood or PRP through a collagen-coated microchannel that had been treated with NP-SILY, and then probing for adherent platelets. Fig. 5 shows that NP-SILY was effective at preventing binding in both the whole blood and PRP. As shown in Fig. 5b, the highest tested concentration of NP-SILY reduced binding by 44% in whole blood. Interestingly, binding was further reduced at lower treatment concentrations, with 2 mg/mL doses reducing binding by 53% and 59% in whole blood and PRP respectively. This trend continued at the lowest concentration with 1 mg/mL NP-SILY reducing binding by 67% in whole blood. As can be seen in Fig. 5a, whole blood yielded larger clusters of bound cells compared to the PRP. This is likely due to the larger overall concentration of cells as well as the presence of red blood cells, which bind to denuded endothe-

**Fig. 3.** NP-SILY binding to naturally elaborated collagen. 3A: Binding of NP-SILY biotin to collagen elaborated by cultured smooth muscle cells. Cells were treated for 30 min or 24 h at 37 °C. 3B: Overlay images of fluorescent NP-SILY (A, B, C, D) and NP-LFA (E, F, G, H) binding to collagen elaborated by smooth muscle cells. Cells were treated for 30 min (A, E, C, G) or 24 h (B, F, D, H) at 1 mg/mL (A, B, E, F) and 2 mg/mL (C, D, G, H) of modified NPs. Scale bar = 50  $\mu$ m. 3C: Semi-quantitative image analysis of the fluorescent area of nanoparticle binding. \*Indicates significance compared to LFA-modified nanoparticles at the same treatment concentration and time.

lium in the presence of bound platelets and have also been shown to enhance platelet binding [53]. Additionally, binding of platelets and red blood cells could have induced soft clot formation which could account for the large clusters of cells observed in Fig. 5A I and II.

#### 4. Discussion

Percutaneous transluminal angioplasty is one of the most common methods used to treat severe PAD. However, deployment of the balloon damages the endothelial layer, exposing the underlying

**Fig. 4.** Anti-inflammatory effects of KAFAK-loaded NP-SILY. Inhibition of inflammation (measured by IL-6) in endothelial cells (4A) and smooth muscle cells (4B). Cells were treated for 24 h at 37 °C. \*Represents significant differences in IL-6 levels between groups indicated by brackets.

collagenous tissue. Platelet adhesion and activation on this collagen results in the release of proinflammatory factors that lead to SMC activation and eventual intimal hyperplasia and restenosis [9,13–16]. Here, we demonstrate that a sulfated collagen-binding poly(NIPAm-MBA-AMPS-AAC) nanoparticle, modified with the collagen-binding peptide SILY is able to bind to a collagenous matrix while preventing platelet adhesion and releasing therapeutic concentrations of cell-penetrating anti-inflammatory peptides. Previous work with SILY-modified peptidoglycans indicates that

because SILY is derived from the platelet receptor to collagen it is able to competitively inhibit platelet binding to collagen. Additionally, when attached to a large macromolecule, prevention of platelet adhesion occurs through a combination of competitive binding to the collagen as well as steric hindrance provided by the overall size of the bound molecule [49]. A key benefit of preventing the platelet adhesion and subsequent activation is that it attenuates the inflammatory cascade at the initiating event, as opposed to attempting to mitigate the downstream results. Previous studies with collagen binding peptidoglycans have demonstrated that protecting the collagenous layer of the damaged vessel leads to reduced platelet deposition and intimal hyperplasia. These previous studies suggest that our modified nanoparticle has the potential to inhibit the increased SMC migration that is caused by the activated platelets, possibly resulting in decreased intimal hyperplasia and reduced risk of restenosis [49,50].

While previous work has demonstrated the biocompatibility of pNIPAM nanoparticles, eliciting low cytotoxicity when taken up by macrophages as well as showing excellent hemocompatibility [38,54,55], the surface addition of the collagen-binding peptide SILY has the potential to alter cellular uptake as well as biocompatibility. Additionally, as these modified particles are designed to be administered via porous balloon catheter directly to the damaged vascular environment, which contains migrating endothelial cells as well as proliferating SMC, they must not elicit cytotoxicity if taken up by either cell type. The results of our cytotoxicity analysis indicate that nanoparticles retained biocompatibility with both endothelial and smooth muscle cells at concentrations up to 8 mg/mL, which exceeds the concentration necessary to release therapeutic concentrations of KAFAK *in vitro*.

In addition to retaining biocompatibility, the modified nanoparticles must not interfere with the natural regeneration of the endothelial layer, which can occur one week following balloon angioplasty [9]. To this end, we tested endothelial migration on EC seeded on tissue culture plastic as well as a collagen-coated surface. We observed no change in migration of EC seeded on tissue culture plastic at treatment concentrations below 4 mg/mL; however, migration was significantly reduced at higher treatment concentrations. This is likely due to nonspecific binding of the nanoparticles to the tissue culture-treated surface, thus creating a negatively charged surface, which has been shown to reduce endothelial adhesion and migration [56]. Of greater concern is the possibility that nanoparticles bound to a collagen surface may provide a barrier to endothelial migration, resulting in decreased migration rates and, thus, impaired healing of the endothelial layer. Interestingly, collagen-bound nanoparticles increased endothelial migration at treatment concentrations above 1 mg/mL, suggesting that these particles may accelerate endothelial regeneration following angioplasty. A similar increase in endothelial migration was observed in SILY-modified glycosaminoglycans [17], where the increased migration was attributed to the molecules' ability to sequester proliferative growth factors such as fibroblast growth factor-2 (FGF-2). Given the charged nature of the modified nanoparticle, it is possible that a similar mechanism is occurring here; the nanoparticles may act as a reservoir of FGF-2 and other positively charged growth factors, thereby increasing its local concentration and accelerating endothelial migration. Upon visualization of migrating endothelial cells, we observed the presence of migrating cells in the center of the well with markedly fewer cells where the silicone plug was in contact with the surface. This is likely due to damage to the collagen coating following plug removal. This damage would decrease the cells ability to remain adherent to the surface when the collagen layer was disrupted, resulting in the ring of lower cell density that we observed.

While NP-SILY's ability to bind to a collagen-coated surface has been demonstrated previously [51], it is equally important to have

**Fig. 5.** NP-SILY inhibition of cellular adhesion under flow. 5A: Images of fluorescently labeled cells bound to a collagen-coated surface, (I, II, V, VI) untreated or (III, IV, VII, VIII) treated for 30 min with 2 mg/mL NP-SILY, following tangential flow of whole blood (I, II, III, IV) or platelet-rich plasma (PRP) (V, VI, VII, VIII). Scale bar = 200  $\mu$ m. 5B: Semi-quantitative image analysis of the fluorescent area of cell tracker-labeled cells shown in 5A. \* indicates significance from untreated surface; † indicates significance from 1 mg/mL treatment.

the ability to bind to collagen that is organized into a more biologically relevant 3-dimensional matrix. In the body, smooth muscle cells control the elaboration and organization of the collagenous matrix through their expression of integrins and matrix metalloproteinases [13,57,58]. To test the ability of SILY-modified nanoparticles to bind to this matrix, we cultured SMC on tissue culture plastic and observed particle binding after 30 min and 24 h of treatment in both the quantitative NP-SILY<sub>biotin</sub> assay and the semi-quantitative fluorescent image analysis. Interestingly, particle binding in globular forms was observed farther away from the cells after 24 h (48 h after seeding) indicating that the particles were able to bind to the collagen as it was secreted by the cells. Additionally, the particles retained their binding ability even after 24 h in media containing 5% FBS. This indicates that the bound SILY was not proteolytically degraded, nor did the presence and adsorption of serum proteins inhibit SILY's binding affinity. In contrast to the NP binding observed for NP-SILY<sub>biotin</sub>, we did not observe a similar biotin signal for NP-LFA<sub>biotin</sub>, which was as expected for the negative control NP. However, using fluorescence microscopy, we observed fluorescence in SMC that were treated with fluorescent NP-LFA for 24 h. Interestingly, in contrast to NP-SILY, the fluorescent signal for the NP-LFA was intracellular, with no extracellular fluorescence observed. This indicates that the NP-LFA particles were internalized by the SMC, as the streptavidin

assay used with the biotinylated NP-LFA particles yielded minimal signal due to the inability of streptavidin to penetrate the cell membrane and bind to the internalized biotinylated particles. Importantly, this demonstrates that conjugation of SILY and subsequent binding of the NP-SILY to collagen prevented cellular uptake of the nanoparticles, meaning that they would remain in the extracellular matrix where they would be able to release therapeutic peptides into the inflamed environment.

Once bound to collagen, the NP-SILY is designed to competitively inhibit collagen-induced platelet adhesion and activation. While this has been demonstrated in a static collagen-coated plate [51], the presence of a flow-induced shear force has the potential to cause delamination of the collagen-bound nanoparticles and with it their platelet inhibition. Whole blood flow experiments, at physiologically relevant flow rates, demonstrated an inversely proportional dose-dependent decrease in cell binding between 44% and 67%. Similarly, flow experiments with PRP at 2 mg/mL yielded a 59% reduction in bound platelets. It should be noted that the measurements taken in whole blood included total binding of multiple cell types and thus were not specific to platelets. These results are consistent with our previous work that shows that platelet inhibition was highest at 2 mg/mL, suggesting that high concentrations of bound particles may increase cellular interaction possibly by changing the charge properties of the surface or

through a surface roughening effect which could disrupt surface flow and increase cellular interaction. This will need to be carefully evaluated *in vivo* in future studies. When taken together with the measured reduction in platelet binding, this data indicates that, at appropriate concentrations, the barrier formed by the NP-SILY is not only effective at reducing platelet adhesion, but provides a general protective layer that prevents other cellular interactions with the collagen surface. While specific measurements of nanoparticle binding under flow were not obtained, nanoparticle detachment is not expected to present a problem given the numerous SILY peptides per nanoparticle. Additionally, the optimal time to administer the nanoparticles would be during the angioplasty procedure, before any platelet adhesion has occurred. This could most easily be accomplished through the use of a porous angioplasty balloon, which has been used to deliver therapeutics such as paclitaxel, thrombolytic agents [59], and nanoparticles [60]. During administration the balloon is in contact with the vessel wall, resulting in minimal flow which enables optimal nanoparticle binding to the denuded surface in a static environment. While the differences in *in vitro* and *in vivo* binding time are a limitation of this study, with the nanoparticles having less time to bind when administered through a balloon, the peptide's high binding affinity combined with the force generated by the balloon against the vessel wall leads us to expect that the nanoparticles will be able to coat the vessel prior to balloon withdrawal.

Once bound, the nanoparticles are designed to act as a platform for the controlled release of anti-inflammatory cell-penetrating peptides. The local release of these peptides into the damaged vessel would attenuate inflammation induced by mechanical damage caused by balloon deployment. Combined with the reduction in platelet binding and activation these nanoparticles can act as a dual therapy platform, inhibiting platelet binding-induced damage while releasing therapeutics to treat the underlying inflammatory state. We tested the ability of these particles to load and release the peptide KFAK in the presence of inflamed smooth muscle and endothelial cells. In these tests, the particles successfully reduced inflammation measured by the production of IL-6. Treatment with KFAK-loaded NP-SILY effectively reduced IL-6 levels by 30% in inflamed endothelial cells, while free KFAK reduced inflammation by 80%. It appears that the KFAK-loaded NP-SILY treatment was less effective than free-KFAK, suggesting that the delivered KFAK dose could be below the therapeutic range specific for endothelial cells; this indicates that cell-specific dose optimization may be required. Alternatively, since the EC media contained less serum than SMC media (2% vs. 5%) creating a less proteolytic environment, it is possible that decreased free-KFAK degradation led to a higher therapeutic response. Given that SMC are a large component of the inflammatory cascade, and that their migration can directly lead to restenosis, it is of paramount importance that these particles effectively treat inflamed SMC. To this end, treatment with KFAK-loaded particles reduced IL-6 production 40%, back to basal levels after 24 h. Previous *in vitro* studies using these peptides have shown a 30  $\mu$ M dose inhibits inflammation in mesothelial cells to a similar degree to what we observed in our smooth muscle cells [30]. *In vivo* studies have also demonstrated significant reductions in inflammation following topical administrations of low doses of similar anti-inflammatory MK2 inhibitor peptides [61,62]. Because of this, we expect similar results when we proceed to *in vivo* studies, due to the particles ability to both inhibit platelet adhesion and activation and reduce inflammation [51]. While there is some concern that *in vivo* delivery would result in rapid removal of KFAK from the damaged area, the use of a cell-penetrating peptide helps to mitigate this concern. Previous *in vivo* studies indicate that the presence of a cell-penetrating domain facilitates rapid and active uptake into cells, suggesting that it should be able to exert

its biological activity prior to being removed from the damaged area [30,61–63].

## 5. Conclusion

We have developed a biocompatible dual therapy collagen-binding poly(NIPAm-MBA-AMPS-AAc) nanoparticle that is able to prevent platelet binding and activation while releasing therapeutic doses of the anti-inflammatory cell-penetrating peptide KFAK. *In vitro* inflammatory models show that treatment with KFAK-loaded nanoparticles significantly reduced pro-inflammatory cytokine levels in both inflamed SMC and endothelial cells. Building on our previous work that demonstrated a greater than 60% inhibition in collagen-induced platelet activation [51] nanoparticles at 1 mg/mL reduced cellular adhesion (red blood cells, leukocytes, and platelets) and platelet adhesion to a collagen surface by 67% and 59% respectively under biologically relevant flow conditions, indicating their potential to attenuate the inflammatory cascade initiated by platelet adhesion and activation. Finally, NP-SILY is able to bind to the collagenous matrix elaborated by SMC, avoiding uptake of the nanoparticles by proliferating SMC and allowing local the release of KFAK into the damaged area. Combined, these properties indicate NP-SILY's potential as a dual therapy platform that is able to inhibit restenosis of a treated vessel by attenuating the platelet activation-induced inflammatory cascade while simultaneously delivering therapeutic peptides to inhibit the inflammatory response of cells damaged by balloon deployment. Future work will focus on characterizing the particles potential for site-specific delivery via porous catheter balloon, as well as its ability to bind to the denuded endothelium of an explanted porcine carotid artery. Additionally, *in vivo* studies will need to be conducted to confirm that KFAK-loaded NP-SILY is a viable option for the inhibition of restenosis following balloon angioplasty, specifically looking for a reduction in intimal hyperplasia and a decrease in platelet and macrophage deposition.

## Disclosures

Moerae Matrix, Inc. has a worldwide exclusive license to the MK2 inhibitor peptide. Alyssa Panitch owns greater than 5% of Moerae Matrix, Inc.

## Funding

This work was supported by the National Institutes of Health [HL106792]. Funding sources had no involvement in study design, collection and analysis of data, or decision to publish.
